Edited by Ralph R. Isberg, Howard Hughes Medical Institute and Tufts University School of Medicine, Boston, MA, and approved November 13, 2017 (received for review August 30, 2017)

Microbial pathogens employ sophisticated virulence strategies to cause infections in humans. The intracellular pathogen *Legionella pneumophila* encodes RidL to hijack the host scaffold protein VPS29, a component of retromer and retriever complexes critical for endosomal cargo recycling. Here, we determined the crystal structure of *L. pneumophila* RidL in complex with the human VPS29–VPS35 retromer subcomplex. A hairpin loop protruding from RidL inserts into a conserved pocket on VPS29 that is also used by cellular ligands, such as Tre-2/Bub2/Cdc16 domain family member 5 (TBC1D5) and VPS9-ankyrin repeat protein for VPS29 binding. Consistent with the idea of molecular mimicry in protein interactions, RidL outcompeted TBC1D5 for binding to VPS29. Furthermore, the interaction of RidL with retromer did not interfere with retromer dimerization but was essential for association of RidL with retromer-coated vacuolar and tubular endosomes. Our work thus provides structural and mechanistic evidence into how RidL is targeted to endosomal membranes.

Endosomal trafficking is a dynamic process by which cells modulate a wide array of physiological functions, including nutrient uptake, cellular polarization, cytokinesis, neural signaling, development, and the innate immune response. Sorting of integral membrane proteins and associated macromolecules, termed “cargos,” from endosomes requires complex molecular machineries that, through multiple lipid–lipid and protein–protein interactions, bind to cargo and deform the membrane into a coated bud (3–5). Retromer is a coat complex that assembles on endosomes and forms tubular carriers for the delivery of recycled material to the plasma membrane, the trans-Golgi network, or other specialized organelles (6, 7). The retromer complex comprises a conserved VPS26–VPS29–VPS35 heterotrimer (with two VPS26 variants, VPS26A and VPS26B) that, in combination with various sorting nexin (SNX) proteins, is recruited to endosomal membranes to select cargo (8–10). The SNX family is a diverse group of proteins characterized by the presence of a phox homology domain that binds primarily to phosphatidylinositol 3-phosphate (PI3P) to target the proteins to the membrane (5, 11). Of the 33 SNXs described in mammals, 7 have been identified as putative retromer interactors: SNX1, SNX2, SNX5, SNX6, SNX27, SNX3, and SNX12. Retromer does not have intrinsic membrane-binding activity and thus relies on its association with SNXs, transmembrane cargo proteins, and the small GTPase Rab7 for recruitment to endosomes (12–15). Although the affinity of retromer for Rab7 is weak, simultaneous interactions with SNXs and cargo combined with retromer oligomerization most likely provide an avidity effect for a strong yet reversible interaction.

Other accessory proteins that directly interact with retromer and regulate endosomal trafficking include the FAM21 subunit of the WASH actin nucleation complex (16), the adaptor VPS9-ankyrin repeat protein (VARP) (17) that binds to the R-SNARE VAMP7 together with several Rab GTPases that function along distinct trafficking pathways (18), and the Tre-2/Bub2/Cdc16 domain family member 5 (TBC1D5), a GTPase-activating protein (GAP) that causes Rab7 inactivation and redistribution to the cytosol (14).

Recent biochemical and structural characterization of single subunits and subcomplexes from retromer have provided insights into its modular architecture and mechanisms of action. VPS35 adopts an elongated α-helical solenoid structure with some bending capability around the midsection, and functions as a platform on which VPS26 and VPS29 bind independently at opposite ends (19, 20). VPS26 adopts an arrestin-like fold (21, 22), interacts with the VPS35 N-terminal side, and—in complex with SNX3—functions as a cargo adaptor for the canonical recycling motif ÖX(L/M) (where Ö is an aromatic amino acid) that mediates retromer-dependent sorting (20). In addition, association of Rab7 with the VPS35 N-terminal side enhances the interaction with cargo (15). VPS26 also interacts with the SNX27 PDZ domain for recruiting cargo proteins containing a type 1 PDZ domain-binding motif (23, 24). VPS29 has a metallophosphoesterase fold with two conserved surface patches at opposite sides (25, 26).

**Significance**

Deciphering microbial virulence mechanisms is of fundamental importance for the treatment of infectious diseases. *Legionella pneumophila*, the causative agent of Legionnaires’ pneumonia, hijacks a variety of host cell factors during intracellular growth. Herein, we uncovered the molecular mechanism by which the *L. pneumophila* effector RidL targets the host VPS29, a scaffolding protein of endosome-associated sorting machineries. Using X-ray crystallography, we determined the structure of RidL, both alone and in complex with retromer. We found that RidL uses a hairpin loop similar to that present in cellular ligands to interact with retromer. This sophisticated molecular mimicry allows RidL to outcompete cellular ligands for retromer binding, explaining how *L. pneumophila* utilizes the endosomal sorting machinery to facilitate targeting of effector proteins.

The VPS35 C-terminal side interacts with the patch around the incomplete catalytic site of VPS29 and occludes it (19), whereas the opposite conserved patch interacts with two cysteine-rich zinc-binding motifs of VARP (17), and an extended loop (Ins1) from the TBC GAP domain of TBCD5 (TBC1D5P1c) (27). Thus, the VPS26 side of retromer contributes both directly and indirectly to cargo recognition and membrane docking in combination with different SNXs, whereas the VPS29 side functions as scaffold for distribution and association with distinct accessory proteins that regulate retromer activity.

The exploitation of recycling endosomal transport by viral and bacterial pathogens is an emerging strategy used to evade degradation and to promote replication during infection (28). Given their biological importance and high level of conservation, it is not surprising that retromer and retromer-associated proteins are opportune targets of a variety of microbial proteins. Some examples include the envelope glycoprotein of the HIV type-1 that binds directly to retromer for endosome-to-Golgi transport (29), the capsid protein L2 of the human papillomavirus type 16 that binds to the PDZ domain of SNX27 for virion trafficking to the nucleus (30, 31), the tyrosine kinase-interacting (Tip) protein of the herpesvirus saimiri that interacts with the retromer subunit VPS35 to impair cation-independent mannose 6-phosphate receptor (CI-MPR) trafficking and down-regulate CD4 surface expression (32), and the effector LE of Chlamydia trachomatis that binds to SNX5/6 and disrupts CI-MPR trafficking (33–35).

Another bacterium that hijacks host cell retromer function is Legionella pneumophila. Upon phagocytosis by host cells, such as freshwater amoeba in the environment or alveolar macrophages during infection, the intravacuolar pathogen dictates the fate of the membrane compartment in which it resides (36). It inhibits fusion of the Legionella-containing vacuole (LCV) with endosomes and lysosomes (37), and instead promotes interaction with host vesicles from the early secretory pathway and other yet to be identified membrane compartments (38–40). In doing so, L. pneumophila creates a camouflaged intracellular replicative niche that supports its survival and replication (36). During infection, L. pneumophila delivers close to 300 proteins, called effectors, into the host cytosol via a specialized translocation apparatus termed the Dot/Icm type IV secretion system (T4SS) (41). The collective activity of these effectors subverts host processes and signaling pathways, including gene expression, metabolism, and vesicle trafficking to promote intracellular proliferation of L. pneumophila (42). Despite extensive efforts, most L. pneumophila effectors have not been characterized in detail and their mode of action has remained unknown.

RidL (Lpg2311/Ceg28) is a 1,167-amino acid protein that, like most L. pneumophila effectors, lacks sequence homology to known proteins (43). Recent studies revealed that RidL interacts with the VPS29 subunit of retromer, localizes to LCVs, and promotes intracellular replication of L. pneumophila within amoeba and macrophages (44). Considering that depletion of retromer components increases L. pneumophila growth, and ectopically produced RidL reduces retrograde trafficking, it was proposed that RidL might restrict retromer function (44). Nonetheless, despite the significance of the RidL–retromer interaction in bacterial infection, the molecular details and mechanistic implications remain unknown. In this work, we performed a comprehensive analysis of the RidL–retromer complex at a structural, molecular, and cellular level and discovered a remarkable mode of molecular mimicry used by RidL for specific subcellular membrane targeting through VPS29 interaction.

Results

The N-Terminal Region of RidL Mediates the Interaction with Retromer. The primary structure of RidL has no significant homology to other proteins that could facilitate the identification of functional domains. Thus, we performed experiments to identify the regions in RidL that are important for binding to retromer. Guided by secondary structure predictions, we created truncated forms of ridL, purified the corresponding proteins from Escherichia coli, and tested their ability to interact with retromer in pull-down assays. We found that only those fragments containing the N-terminal region spanning amino acids 30–236 interacted with a stable retromer subcomplex (VPS29–VPS35C) composed of VPS29 and the C-terminal region of VPS35 (amino acids 476–780) (Fig. 1 A and B). Fragments comprising the central (RidL<sub>1–866</sub>) or C-terminal region (RidL<sub>867–1167</sub>) of RidL, or GST alone (control), did not bind VPS29–VPS35C (Fig. 1B). Similar observations were made by size-exclusion chromatography (SEC), where full-length RidL or RidL<sub>1–236</sub> coeluted with retromer, the VPS29–VPS35C subcomplex, or monomeric VPS29, while the peak containing RidL<sub>1–866</sub> migrated separate from the peak of the VPS29–VPS35C subcomplex (Fig. S1). Since neither RidL<sub>1–866</sub> nor RidL<sub>867–1167</sub> showed any noticeable reduction in stability or solubility compared with RidL, it is unlikely that failure to bind RidL was due to their misfolding. Taken together, these analyses demonstrated that RidL<sub>1–236</sub> was the smallest fragment tested here that stably interacted with VPS29.

Next, we compared the binding affinity (K<sub>d</sub>) of RidL with that of an N-terminal fragment (amino acids 30–236) of RidL (RidL<sub>30–236</sub>) for retromer (VPS29–VPS35) by isothermal titration calorimetry (ITC). We chose to use full-length RidL<sub>1–236</sub> over RidL<sub>1–236</sub> for the ITC analysis because of better purification yields. The affinities of RidL (K<sub>d</sub> = 151 nM) and RidL<sub>1–236</sub> (K<sub>d</sub> = 164 nM) for retromer were similar, indicating that retromer binding was mediated mainly by the N-terminal region of RidL, and that no other region of RidL made a major contribution to complex formation (Fig. 1C). Furthermore, the affinities of RidL for either retromer, the VPS29–VPS35C subcomplex, or the monomeric VPS29 subunit were almost identical (K<sub>d</sub> retromer = 151 nM; K<sub>d</sub> VPS29–VPS35C = 151 nM; K<sub>d</sub> VPS29 = 181 nM) (Fig. 1D), suggesting that binding of RidL to retromer occurred mainly, if not exclusively, through VPS29 independent of other retromer subunits. These results are fully consistent with the previously reported coinmunoprecipitation assays describing the VPS29–RidL interaction (44), and further extend the precise mapping of RidL<sub>30–236</sub> as the region responsible for contacting the VPS29 subunit of retromer.

Structure of RidL<sub>1–866</sub>. To further investigate the molecular basis for the binding of RidL to retromer, we initiated the structural characterization of the complex by X-ray crystallography. Initial attempts using either retromer, the VPS29–VPS35C subcomplex or the VPS29 subunit bound to different RidL constructs, yielded either no crystals or crystals with poor diffraction quality. The best crystals, obtained with the VPS29–VPS35C subcomplex and RidL<sub>1–236</sub> diffraction to 4.3 Å. At this stage, molecular replacement using the structure of the VPS29–VPS35C subcomplex (PDB ID code 2R17) provided a clear solution with four VPS35C–VPS29 molecules per asymmetric unit showing partial-difference electron density for RidL<sub>1–236</sub>. However, the lack of high-resolution data precluded the iterative refinement and model-building steps necessary to extract structural information for RidL<sub>1–236</sub>. Thus, we focused on obtaining a higher-resolution structure of uncomplexed RidL. The construct of RidL encompassing amino acids 1–866 (RidL<sub>1–866</sub>) produces well-diffracting crystals. The structure was solved by single-wavelength anomalous diffraction using selenium as the anomalous scatterer and refined to 3.0-Å resolution (Fig. 2A, Fig. S2A and B, and Table S1).

The structure of RidL<sub>1–866</sub> corresponds to an all-α protein formed by 47 α-helices (Fig. 2 A and B). The overall structure adopts an S-shape with a length of 120 Å and a width of 50 Å at the top and 85 Å at the base (Fig. 2A). RidL<sub>1–866</sub> showed no obvious structural similarity to any known entry in the protein database.
data bank [Dali server analysis (45)]. An alternative subdomain analysis also revealed no significant resemblance to other known domains except for the terminal three-helix bundle (amino acids 712–863) for which the sequence identity with the top matches was very low (less than 13%), thus limiting the prediction of potential functions for RidL (Fig. 2 B and C).

**Fig. 2.** Structure of RidL-866. (A) Overall structure of RidL-866 (green) represented by a ribbon diagram with transparent surface. The loop segment (residues 163–176) through which binding to VPS29 occurs is marked with an arrow. Topology diagram of RidL-866 (B) and ribbon diagram (C) colored on the basis of the different predicted domains: green (residues 6–262), orange (residues 263–429), blue (residues 430–711), red (residues 712–863), and magenta (residues 163–176).
Crystal Structure of RidL_{1-236} Bound to the VPS29–VPS35C Subcomplex. With the 3.0-Å resolution structure of RidL_{1-236} (Fig. 2) on hand, we used its RidL_{1-236} and the VPS35C–VPS29 structure (PDB ID code 2R17) as models for the molecular-replacement solution of the aforementioned 4.3-Å hetero-trimeric RidL_{1-236}–VPS29–VPS35C complex. The final structure has a free R-factor of 29.4 and good stereochemistry (Fig. S2 C and D and Table S1). The crystals contain four copies of each RidL_{1-236} and VPS29–VPS35C in the asymmetric unit. Each RidL_{1-236} molecule establishes contacts with two copies of VPS35C at different sites and a single contact with VPS29. The RidL_{1-236}–VPS29–VPS35C interaction occurs via a protruding hairpin loop of RidL (amino acids 163–176) that binds to a hydrophobic pocket on the surface of VPS29 opposite to the VPS29–VPS35C interface (Fig. 3 A). Notably, no other region of RidL_{1-236} establishes a direct contact with VPS29, suggesting that the interaction solely relies on the hairpin loop. Based on this observation, we crystallized a peptide comprising the entire hairpin loop (RidL_{loop}, residues 163KEETPTIPPKAIN_{176}) with VPS29–VPS35C, and determined the structure of the complex at 2.5-Å resolution (Fig. 3B and Table S1). The difference Fourier map shows clear electron density for the RidL peptide, with most side chains being well defined (Fig. S2 E and F). Overall, recognition of the hydrophobic pocket of VPS29 by RidL_{loop} covers a surface area of 420 Å^2 and is dominated by hydrophobic interactions (Fig. 3 C and D). The side chains P168, I170, and P172 at the edge of the hairpin loop of RidL are the most-buried residues upon complex formation and are at the center of the interface. P168 interacts with a shallow hydrophobic pocket formed by L25, V172, and V174 of VPS29. The carbonyl group of the main chain of T169 establishes a hydrogen bond with Y165 of VPS29. The side chain of I170 inserts deep into a cavity formed by L2, L25, L26, K30, L31, L152, and Y165 of VPS29. The next residue in the hairpin loop, P171 further contributes to the burial of I170, making hydrophobic contacts with L2 and L152 of VPS29, while also helping to position the following P172 in a ring–ring stacking interaction with Y163 of VPS29. In addition, the interaction is reinforced with a hydrogen bond between Y166 of RidL and R176 of VPS29. More peripherally, Y166 of RidL is buried between the crossing segment of the hairpin loop and a shallow hydrophobic pocket formed by Y163, V174, and R176 of VPS29, thus providing an extended flat contact that further stabilizes the hairpin conformation. Importantly, a comparison between the primary sequences of VPS29 from human (the disease host) and other metazoa, including amoebae (the environmental host), showed that all VPS29 residues at the contact site are highly conserved (Fig. 3E and Fig. S3), suggesting that the interaction between RidL and VPS29 has the same binding mode in all hosts.

Overall Assembly of the RidL–Retromer Complex in Solution. The structure of RidL_{1-236} bound to the VPS29–VPS35C subcomplex presented here (Fig. 3) revealed two elongated macromolecules connected via a single-point junction. Interestingly, upon comparison of the structures of RidL_{1-236} alone and RidL_{1-236} bound to VPS29–VPS35C, it became clear that the orientation of the RidL hairpin loop involved in the interaction with VPS29 remained essentially unaltered, despite the different crystallization conditions and crystal packing interactions. To capture the global shape of the RidL–retromer complex, we performed small-angle X-ray scattering (SAXS) experiments and ab initio reconstructions. We obtained representative bead models with low average spatial discrepancy from two samples, RidL_{1-236}–VPS29–VPS35C and RidL_{1-236}–retromer (Fig. 4A and B and Fig. S4 A–D). While the bead-model shape of RidL_{1-236}–VPS29–VPS35C was elongated and twisted with two protruding edges, the bead-model of RidL_{1-236}–retromer exhibited an elbow-shaped rod. Rigid-body refinement on the bead models using the crystal structures of RidL_{1-236} (present study) and VPS29–VPS35C (19) (Fig. 4A, or RidL_{1-236}–VPS29–VPS35C (present study) and VPS26–VPS35N (20) (Fig. 4B) resulted in a very good fit between the theoretical scattering profiles for each macromolecular model and the experimental SAXS data (Fig. 4A and B and Fig. S4 A and B). Superposition of both models yielded a complete RidL_{1-236}–retromer ensemble with a distinctive V-architecture (Fig. 4C). However, attempts to obtain a bead-model with RidL_{1-236}–retromer failed to converge on a single best-fit conformation, which might be indicative of a multiconformational equilibrium. In this scenario, the composite RidL_{1-236}–retromer ensemble would represent a conformational snapshot between fluctuating states.

Previous studies have demonstrated that retromer can form dimers through the VPS29 side ends at high protein concentration and physiologival ionic strength (20, 46). Although the molecular details for the dimerization remain unknown, it has been speculated that the self-dimerization propensity could contribute to retromer coat assembly (20). Given that RidL interacted with retromer through the VPS29 subunit, we wondered whether RidL affects retromer dimerization. Using SEC in-line multiance light scattering (SEC-MALS), we characterized the molecular mass for each complex. Interestingly, RidL behaved as a monomer under physiological ionic strength, but when incubated with retromer, the complex exhibited a molar mass consistent with a 2:2 oligomer, thus allowing the formation of retromer dimers. In contrast, when RidL was incubated with monomeric retromer in a high ionic strength buffer, the molar mass was consistent with a 1:1 complex (Fig. S4 E–G).
truncation of the loop in RidL (RidL_{Δ1}) resulted in a complete loss of binding, underscoring the critical importance of the hydrophobic and hydrogen bond interactions for the formation of a stable VPS29–RidL complex. We also evaluated the interaction between the synthetic RidL_{loop} peptide (residues 163–176) and VPS29 but detected no binding by ITC, most likely because the peptide does not form the hairpin structure in solution that is critical for the recognition process. Finally, we tested the interaction between full-length RidL and the retromer complex containing either VPS29, VPS29_{Y163A} or VPS29_{Y165A} (Fig. 5C and Fig. S5C). Unlike wild-type retromer, retromer containing VPS29_{Y163A} or VPS29_{Y165A} failed to interact with RidL, further confirming that the crystal contacts observed between RidL_{Δ1} and VPS29–RidL35C are indeed relevant for complex formation between RidL and retromer.

**RidL Localizes to Endosomal Membranes Occupied by Retromer.** To assess if the interactions between RidL and retromer observed in vitro (Figs. 3 and 5) are also relevant in cells, we used fluorescence microscopy to examine the distribution of GFP-RidL–encoding constructs expressed by transient transfection in HeLa cells. Live-cell imaging of the transfected cells showed that the signal for full-length GFP-RidL was barely detectable. In contrast, a GFP-tagged, N-terminal RidL fragment comprising amino acids 1–236 (GFP-RidL_{Δ1–236}) was produced at high levels and displayed a punctate cytoplasmic localization (Fig. 6A). Additional studies in fixed HeLa cells revealed that the cytoplasmic puncta containing GFP–RidL_{Δ1–236} colocalized with the endogenous VPS26 subunit of retromer (Fig. 6B and C). Simultaneous production of either GFP- or mCherry-tagged RidL_{Δ1–236} with differently tagged forms of other organelar markers in live cells showed colocalization of RidL_{Δ1–236} with the VPS29 subunit of retromer (Fig. 6D and E) and the endosomal proteins early endosome antigen 1 (EEA1), Rab5, and SNX12, but not the trans-Golgi network protein TGN38 (Fig. 6D and E and Fig. S6A). Continuous live-cell imaging further revealed that mCherry-RidL_{Δ1–236} colocalized with YFP-VPS29 on vacuolar endosomes as well as dynamic tubules emanating from those endosomes (Fig. 6D, Inset, and Movie S1). EEA1-GFP also exhibited significant colocalization with mCherry-RidL_{Δ1–236} on the vacuolar part of endosomes but, unlike YFP-VPS29, it was not associated with the budding tubules (Fig. 6D, Inset, and Movie S2). Together, these studies demonstrated that exogenously produced RidL_{Δ1–236} specifically localized to vacuolar and tubular endosomes, and that the presence of RidL did not affect retromer localization to those membranous structures.

**RidL Localization to Endosomes Requires VPS29 Binding.** Our in vitro studies revealed that removal of the central region of the hairpin loop (amino acids 166–173) from RidL (RidL_{Δ1}) ablated binding to either monomeric VPS29 or VPS29 as part of the retromer complex (Fig. 5). Hence, we tested if the hairpin loop played an equally important role for endosomal localization of RidL. Upon deletion of the hairpin loop in the context of GFP–RidL_{Δ1–236}, the resulting GFP-tagged mutant protein (GFP–RidL_{Δ1–236,Δ1}) assumed a diffuse cytosolic distribution within cells, with no detectable enrichment on endosomal compartments (Fig. 6A–C and E and Fig. S6B and C). Failure to target to endosomes indicated that binding of RidL to retromer, in particular to VPS29, is essential for its proper localization within cells. To further test this hypothesis, we silenced retromer by RNA interference (RNAi), and analyzed its effect on RidL distribution. In contrast to mock RNAi-treated control cells, knockdown of the VPS35 subunit of retromer prevented association of GFP–RidL_{Δ1–236} but not EEA1, with endosomes (Fig. S7). Taken together, these experiments demonstrated that the interaction of the hairpin loop of RidL with retromer, revealed by our crystallographic and biochemical analyses, is essential for...
association of RidL with retromer-coated vacuolar and tubular endosomes.

**RidL Competes with Cellular Ligands for the Same Binding Site on VPS29.** VPS29 contains two patches of conserved hydrophobic residues on opposite surfaces (25, 26). While one patch was reported to bind VPS35 (19, 25), the opposite patch mediates the association with the Rab7 GAP TBC1D5 (27) and the adaptor protein VARP (17). Interestingly, the pocket on VPS29 for binding TBC1D5 and VARP involves the same cluster of hydrophobic residues found here to interact with RidL (Figs. 3 and 5). Indeed, a comparison between the crystal structures of VPS29 in complex with a peptide derived from TBC1D5/VAP (PDB ID code 5GTU) and the structure of VPS29 in complex with the hairpin loop of RidL (Fig. 3) revealed a common loop pattern with a conserved P-L/I motif as the linchpin of the interactions (residues I170-P171 in RidL; P141-L142 in TBC1D5) (Fig. 7A). Previously reported ITC titration assays of recombinant TBC1D5/VAP or VARP Cys-rich motifs to VPS29 yielded similar $K_d$ values (5–13 μM) for both complexes in the low micromolar range, following a 1:1 stoichiometry (17, 27). As described above, RidL and RidL-ΔL exhibited a 1.5-2 log higher affinity for VPS29 and retromer (151 nM and 181 nM, respectively), which suggests that RidL could compete effectively against endogenous ligands. However, it has also been described that the association of TBC1D5/VAP with retromer involves a binary interaction through both VPS29 and VPS35, with a $K_d$ value of ~220 nM (27) and, thus, closer to that observed herein for RidL binding to retromer (Fig. 1). Our ITC-derived $K_d$ value for the interaction between TBC1D5/retromer was comparable, although slightly higher, to those reported earlier (~450 nM vs. ~220 nM) (27), suggesting a weaker binding of TBC1D5 to retromer than RidL (Fig. S8A–D).

To examine if RidL could compete with TBC1D5/retromer for binding to retromer in solution, a preformed TBC1D5/retromer complex was incubated with an equimolar amount of RidL (Fig. 7B and D), and the mixture was subsequently fractionated by SEC. In the absence of RidL, TBC1D5/VAP and retromer migrated together, with enrichment in the fast-eluting fractions (10.5–12.5 mL). In contrast, upon addition of RidL, TBC1D5/VAP was present almost exclusively in late-eluting fractions (14–15.5 mL), consistent with its displacement from retromer, while RidL coeluted with retromer (Fig. 7B and D). Thus, under the conditions tested here, RidL competed TBC1D5/VAP for binding to retromer. Importantly, the mutant protein RidLΔL was unable to disrupt the preformed TBC1D5/VAP–retromer complex under the same conditions (Fig. 7B and D), indicating that VPS29 binding was required for TBC1D5 displacement. In contrast, incubation of a preformed RidL–retromer complex with an equimolar amount of TBC1D5/VAP did not result in the ejection of RidL from the retromer complex (Fig. S8 E and F), showing that RidL can resist displacement from VPS29 by cellular ligands.

To evaluate if RidL could compete with VARP in solution, we designed a VARP construct containing the two cysteine-rich domains involved in direct binding to VPS29 (VARPc, residues 396–746) and performed ITC and gel-filtration competition analysis. The ITC experiments showed that VARPc associates with retromer with a $K_d$ of ~3 μM and that two independent point mutations on VPS29 (Y165A and Y163A) completely abolished the interaction (Fig. S8 C and D). These results confirmed that VARP associates through the same VPS29 conserved pocket to retromer but with a weaker affinity than RidL. In addition, we analyzed the ability of RidL to displace VARPc from retromer by SEC. Due to the similar molecular weight between VARPc and the VPS26 subunit of retromer, we used a VPS29–VPS35 reconstituted retromer subcomplex to facilitate the visualization of proteins. As expected, RidL competed VARPc for binding to VPS29–VPS35 but the mutant RidLΔL was unable to disrupt the preformed VARPc–VPS29–VPS35 complex (Fig. 7C and E). In contrast, preformed RidL–VPS29–VPS35 complex was not outcompeted by VARPc under the same conditions (Fig. S8 G and H). These experimental results confirm that in solution RidL efficiently competes with VARP for binding to retromer.

We also examined if RidL could displace TBC1D5 from retromer in cells. In agreement with our biochemical experiments,
overproduction of mCherry-RIDL△L1-236, but not mCherry-RIDL△L1-236,ΔL, abrogated the association of GFP-TB1C1D5 with endosomes (Fig. 7F and G). These results demonstrated that RIDL can effectively block a cellular ligand from binding to retromer, both in vitro and in vivo. We also observed weaker VARP-GFP fluorescence on endosomes from mCherry-RIDL△L1-236,ΔL-overproducing cells relative to mCherry-RIDL△L1-236,ΔL-overproducing cells (Fig. S9). However, a fraction of VARP-GFP remained associated with endosomes even in mCherry-RIDL△L1-236,ΔL-overproducing cells (Fig. S9), suggesting that VARP has additional determinants for recruitment to endosomes.

Discussion

In this study, we have determined the structure of the _L. pneumophila_ effector RIDL, both alone and in complex with the human VPS29–VPS35C retromer subcomplex, and deciphered the molecular mechanism by which RIDL is targeted to endosomal membranes. The crystal structure of RIDL△L1-866 is comprised of four domains that show neither sequence nor structural homology to other proteins. Targeting of RIDL to recycling endosomes was solely dependent on a hairpin loop (amino acids 163–176) that binds to a conserved patch of exposed hydrophobic residues on VPS29. Interestingly, the binding mode of RIDL with VPS29 was remarkably similar to that of the endogenous factor TBC1D5 (27). Indeed, TBC1D5 and VARP use the same binding patch on VPS29 for their association with retromer (17, 27) but bind with lower affinities compared with RIDL. Consistent with these results, RIDL effectively competed with TBC1D5 for binding to retromer in vitro, but only partially displaced VARP from endosomes in vivo (Fig. 7 and Fig. S9). This latter observation suggests that VARP has additional means of association with endosomes.

TBC1D5 possesses GAP activity toward Rab7, which has been proposed to promote retromer disassociation from membranes (14). During nutrient starvation, TBC1D5 can also associate with LC3, a protein involved in autophagy, which shuttles it away from its inhibitory interaction with retromer to promote GLUT1 recycling to the plasma membrane (47). These observations are evidence that the binding site on VPS29 may serve as a switch between mutually exclusive interactions to enhance or restrict retromer function within particular trafficking pathways. Furthermore, the recent identification of retriever, a related heterotrimer that shares the VPS29 subunit but recycles different cargoes, provides an even larger diversity of sorting events depending upon VPS29 subunits (48), so it is possible that RIDL recruitment to these subdomains could also involve retriever. Our study suggests that RIDL exploits the conserved pocket on VPS29 through molecular mimicry to efficiently reach specific endosomal subdomains where various cargo-retrieval machineries are located.

Recent studies have shown that _L. pneumophila_ mutants lacking ridL exhibit a mild growth defect in the amoebae host _Dictyostelium discoideum_ as well as in mouse RAW264.7 macrophages, while deletion of some (VPS26A/B, VPS29) but not all retromer subunits by RNA interference caused a subtle stimulation in _L. pneumophila_ growth in HeLa cells (44). Similarly, ectopic production of RIDL in HeLa cells or infection of _L. pneumophila_ with expressed EEA1-GFP, and emanating tubules labeled with YFP-VPS29 but not EEA1-GFP. (C) Colocalization of GFP-RIDL1-236 with VPS26 on endosomal compartments. (Scale bars, 5 μm.) (C) Colocalization of GFP-RIDL1-236 or GFP-RIDL△L1-236,ΔL with endogenous VPS26 in fixed cells was quantified in at least 32 cells across three independent experiments using ImageJ. Pearson’s correlation coefficient values for colocalization in individual cells are shown in the plots (****p < 0.0001 by unpaired t test with equal SD). (D) HeLa cells were cotransfected with plasmids encoding mCherry-RIDL1-236 and either YFP-VPS29 or early endosome marker EEA1-GFP, and imaged live. Still images were taken from Movies S1 (VPS29) and S2 (EEA1). (Scale bars, 5 μm.) Insets show mCherry-RIDL1-236 tubules (magnification: Top, 3.6x; Bottom, 2.5x). Notice the association of mCherry-RIDL1-236 with vacuolar endosomes labeled with YFP-VPS29 and EEA1-GFP, and emanating tubules labeled with YFP-VPS29 but not EEA1-GFP. (E) Colocalization of GFP-RIDL1-236 or GFP-RIDL△L1-236,ΔL with expressed EEA1-GFP, VPS29-YFP, or TGN38-mCherry in live cells was quantified in at least 30 cells across three independent experiments using ImageJ. Pearson’s correlation coefficient values for colocalization in individual cells are shown in the scatter plots (****p < 0.0001, by unpaired t test with equal SD). ns, not significant.
Fig. 7. RidL competes with TBC1D5 for binding to retromer. (A) Superposition of the VPS29/TBC1D5-Ins1 complex (PDB ID code 5GTU) shown in orange and the VPS29–VPS35–RidL∆L complex (green). (B) Upper Gel-filtration chromatogram of the complex formed by retromer and TBC1D5 (black) at a molar ratio of 1:1.5. The chromatograms of retromer (red) and TBC1D5 (brown) are also shown. (Lower) Competition assay between RidL and TBC1D5 for retromer binding. Gel-filtration chromatogram of the complex formed by retromer and TBC1D5 (black), after incubation with RidL at a 1:1 molar ratio (magenta) and after the incubation with RidLΔL (cyan). (C) Upper Gel-filtration chromatogram of the complex formed by VPS29–VPS35 and VARPc (black) at 1:1 molar ratio. The chromatograms of VPS29–VPS35 (red) and VARPc (green) are also shown. (Lower) Competition assay between RidL and VARPc for retromer binding. Gel-filtration chromatogram of the complex formed by VPS29–VPS35 and VARPc (black), after incubation with RidL (magenta) and after the incubation with RidLΔL (cyan). (D and E) Coomassie blue-stained SDS/PAGE gels of the corresponding fractions shown in the chromatograms, with the position of each protein band indicated on the right. Gels with the corresponding fractions of the competition assays between RidL and RidLΔL are shown in the Center and on the Right, respectively. (F) Overexpression of mCherry-RidL1-236, but not mCherry-RidL1-236,ΔL displaces GFP-TBC1D5 from endosomes. HeLa cells were cotransfected with plasmids encoding GFP-TBC1D5 and either mCherry-RidL1-236 or mCherry-RidL1-236,ΔL and imaged live after 24 h. Inset shows endosomal recruitment of either mCherry-RidL1-236 or GFP-TBC1D5 in representative images of three independent repeats (magnification: Top, 1.8x; Bottom, 1.6x). (Scale bars, 5 μm.) (G) A minimum of 45 cells coexpressing GFP-TBC1D5 and either mCherry-RidL1-236, mCherry-RidL1-236,ΔL, or mCherry vector were assessed for association of GFP-TBC1D5 signal with intracellular membranes. Bar graphs report percentage of the cell population displaying membrane-associated GFP-TBC1D5 for each condition in a single matched experiment.
L. pneumophila but not L. pneumophila mutants lacking RidL inhibited retrograde trafficking of subunit B from Shiga toxin or cholera toxin, two well-established model cargos for analyzing retromer-dependent retrograde transport (44). These data hint at a role for retromer in restricting L. pneumophila proliferation, and that RidL is translocated by L. pneumophila to counteract retromer function (44). However, some of the findings presented here argue that RidL has a more nuanced effect on retromer function. For example, although high levels of RidL compete with cellular ligands, such as TBC1D5, for VPS29 binding in transiently transfected HeLa cells (Fig. 7), the number of RidL molecules translocated by a single L. pneumophila bacterium into infected host cells is likely orders-of-magnitude lower than the copy number of retromer molecules, making it improbable that competitive binding to VPS29, which is an abundant protein present in at least two endosomal complexes, will cause a global collapse of endosomal recycling within cells. In addition, our SEC-MALS analyses demonstrated that RidLΔ1-866 binding to retromer did not preclude retromer dimerization (Fig. S4), a process that has been speculated to contribute to coat assembly (20), suggesting that retromer might still be able to assemble into a coat-like lattice on recycling endosomal tubules even in complex with RidL. Furthermore, the presence of exogenous RidL did not disturb the localization of retromer subunits to endosomal membranes or the formation of tubular structures emanating from those compartments (Fig. 6), suggesting that retrograde transport proceeded normally even in the presence of RidL. Thus, our findings support a VPS29-dependent membrane targeting mechanism rather than a widespread inhibitory activity.

Retromer and retriever have been predicted to share similar architecture and to spatially overlap in endosomal subdomains despite interacting with different combinations of SNX proteins for their association with membranes (48). RidL and the SNXs linked to retromer and retriever are PI3P-binding proteins. We have not found structural evidence of a PI3P-binding site in RidLΔ1-866. Despite extensive cocystalization experiments of RidLΔ1-866 with PI3P analogs, we were unable to identify any extra density associated with the protein, possibly due to steric occlusion in the crystal packing, ionic strength in the crystallization solution, or because PI3P binds to the unsolved C-terminal region of RidL (residues 867–1167). Nonetheless, phosphoinositide-binding domains are usually conserved by other protein-binding domains to integrate the simultaneous binding of multiple factors in the same membrane. This sort of coincidence detection can facilitate submembrane localization, increase the apparent affinity due to the avidity effect or trigger a cellular process as part of a multivalent interaction (49).

At this time, we can only speculate about the function of RidL during L. pneumophila infection. RidL is a large effector composed of multiple domains with very low structural similarity to other known proteins; thus, it is probable that concomitant interactions with VPS29 and other, yet unidentified, factors could direct RidL specifically and efficiently to the LCV to interfere with lysosome fusion. This is consistent with the observation that VPS29 localizes to LCVs in a Dot/Icm-dependent, but RidL-independent manner and that LCVs formed by AriDl accumulated more lysosome-associated membrane protein 1 (44). Interestingly, in yeast, the release of the Rab-like Rab7/Ypt7 from retromer favors the interaction with the HOPS tethering complex, which in turn promotes SNARE-dependent fusion of the late endosome with vacuoles (50). Thus, it is conceivable that RidL could prevent Rab7 disassociation from retromer by displacing TBC1D5 to restrain the interaction with the mammalian HOPS-RILP tethering complex (51) and ultimately impede the fusion with lysosomes.

In conclusion, our results have shown that RidL interacts with VPS29 through a hairpin loop closely mimicking the natural TBC1D5 interaction and that this binding targets RidL to sites where retromer is present, most probably outcompeting cellular ligands. These findings mechanistically explain the targeting of RidL to subcellular membrane domains and pave the way for future research to define the ultimate function of RidL during L. pneumophila infection.

Materials and Methods

Recombinant Protein Production. The different constructs encoding RidL (RidLΔ1-220, RidLΔ1-236, RidLΔ1-420, RidLΔ1-866, RidLΔ1-1260, RidLL, RidLΔ1-1260, RidLΔ1-236, human VPS29 and VPS29 mutants (VPS29Δ1635, VPS29Δ1236, VPS29Δ1523), and VARPC (residues 396–746) were cloned into the vector pGST-Parallel2 (52) using restriction enzymes and Gibson assembly. VPS29Δ1635 and VPS29Δ1236 were also cloned into pmr101A (American Type Culture Collection) to form the mutated retromer complex. DNA encoding human TBC1D5 (residues 1–419) was cloned into the pDB-HisGST vector (DNASe ID: EvNO00085134). Production of native proteins was performed in E. coli BL21(DE3), whereas proteins labeled with Seleno-c-methionine (SeMet) were isolated from E. coli B834(DE3), as described previously (20).

Protein Crystallization and Structure Determination. Crystals were grown by hanging-drop vapor diffusion at 18 °C. Native and SeMet derivative crystals of RidLΔ1-866 were obtained by mixing 1 μL of 100–120 μM protein with 1 μL of well solution containing 0.4 M sodium fluoride, 14–16% (wt/vol) polyethylene glycol (PEG) 3350, and 0.1 M Bis-Tris propane pH 7.5. The crystallization of native and SeMet-labeled complexes of RidLΔ1-220–VPS29–VPS33C was achieved by mixing 1 μL of the purified complex at 7.5 mg/mL and 1 μL of the precipitant solution containing 0.1 M sodium chloride, 0.1 M Tris pH 8.0 and 4–8% (vol/vol) PEG6000. The RidLΔ1-866 structure was solved using experimental diffraction data (SeMet MAD data) (41). The structure of the RidLΔ1-220–VPS29–VPS33C complex was solved by molecular replacement combined with SAD phases (SAD-MR) using the known structure of VPS29–VPS33C complex (PDB ID code 2R17) and the anomalous signal of two crystals; one in which the VPS29–VPS33 complex was labeled with SeMet, and the second in which only RidLΔ1-236 was labeled with SeMet. VPS29–VPS33C–RidLΔ1-236 was solved by MR with PHASER using the VPS29–VPS33C complex (PDB ID code 2R17) as a search model. The crystallographic information is summarized in Table S1.

ITC Assays. ITC experiments were conducted on a VP-ITC microcalorimeter (MicroCal) at 25 °C. Before each experiment, proteins were dialyzed overnight at 4 °C against 50 mM Hepes 7.5, 300 mM NaCl, and 0.5 mM TCEP, and degassed for 5 min in a Thermodruck sample degasser before titration. Each experiment involved one initial 2-μL injection (not used in data fitting), followed by 27 injections of 10-μL aliquots with a spacing of 360 s between injections. Data were analyzed using the Origin ITC software package supplied by MicroCal by fitting a “one set of sites” model to the binding isotherm. For the ITC analysis of the binding between RidL and retromer, 80–110 μM RidL (full-length or RidLΔ1-236) was injected into the sample cell containing 9–11 μM of different combinations of retromer subunits (VPS26–VPS29–VPS33, VPS29–VPS33, or VPS29). The analysis of the interaction between RidL and VPS29 was performed by titrating 100–120 μM of RidL into 10 μM of different VPS29 mutants (Y166A, Y163A, L152E, and VPS29–VPS33C, or 150 μM RidLΔL, RidLΔ1-1650, or RidLΔ1-700 into 10 μM VPS29. For the ITC analysis of the binding between TBC1D5 and retromer, 200–220 μM TBC1D5 was titrated into 9–12 μM of the different retromer proteins (retromer, VPS26–VPS29–VPS33C, VPS35, or the different retromer mutants). Finally, the interaction between VARPC and the different retromer proteins was carried out by titrating 140–150 μM into 10 μM of retromer variants. Data are the mean of a minimum of three independent runs for each experiment.

GST-Tagged Pull-Down Experiments. For the identification of the region of RidL that binds to retromer, 20 μM VPS29–GST–VPS33C was incubated with 20 μM RidL or different RidL constructs for 1 h at 4 °C in buffer C. Then, 20 μL of equilibrated Glutathione Sepharose beads (GE Healthcare) were added to 70 μL of the protein mixture and incubated for 1 h at 4 °C with gentle agitation. Beads were washed three times with 1 mL buffer C followed by 5 min centrifugation at 3,000 × g. Bound proteins were eluted with SDS-containing sample buffer, resolved by SDS/PAGE and visualized by Coomassie blue staining.

Precipitation assays with VPS29 mutants were performed following the same protocol as described above but with the GST-tag present on RidL or RidLΔL.

Competitive Binding Assay. For the competition assay, preformed complexes were separated by gel-filtration in buffer C to remove excess protein. The purified complexes were incubated with an equimolar amount of RidL, in the...
case of the complex formed by TBC1D5 and retromer or VARmPC and VARmPC, in the case of the complex of Ridl and retromer. These protein mixtures were once again separated by gel-filtration in buffer E.
